## Abstract

The day-time eastward equatorial electric field (EEF) in the  $E$ -region plays an important role in equatorial ionospheric dynamics. It is responsible for driving the equatorial electrojet (EEJ) current system, equatorial vertical ion drifts, and the equatorial ionization anomaly (EIA). Due to its importance, there is much interest in accurately measuring the EEF. However, there is a severe lack of high quality data with the notable exception being the JULIA coherent scatter radar in Peru. In this work we use CHAMP satellite-derived latitudinal current profiles of the day-time EEJ in order to estimate the eastward electric field at all longitudes, seasons, and day-side local times. We have constructed a dataset of over 32,000 EEF estimates based on six years of CHAMP data. Our estimates agree well with JULIA measurements, with an RMS difference of 0.13 mV/m.

# 1 Introduction

2 Neutral thermospheric winds in the equatorial region provide the energy re-  
3 quired to maintain the zonal equatorial electric field (EEF). In the  $E$ -region,  
4 tidal winds drive currents to higher latitudes, which interact with the Earth's  
5 magnetic field, causing a buildup of positive and negative charges at the dawn  
6 and dusk terminators respectively. This causes a strong eastward electric field  
7 on the equatorial day-side (Forbes, 1981; Heelis, 2004). This electric field is a  
8 primary driver of many ionospheric phenomena.

9 At the magnetic dip equator, the EEF drives a vertical Hall current and an  
10 eastward Pederson current. Since the upper and lower boundaries of the dy-  
11 namo region are practically non-conducting, the Hall current is restricted,  
12 which leads to an enhanced eastward current flow known as the equatorial  
13 electrojet (EEJ) (Cowling, 1933). The EEJ is receiving renewed interest with  
14 the availability of large magnetic data sets from recent satellite missions. Mag-  
15 netic signals of the EEJ current are an important tool to indirectly study the  
16 eastward electric field.

17 The EEF causes vertical  $\mathbf{E} \times \mathbf{B}$  plasma drift upward at the dip equator. This  
18 vertical ion drift lifts equatorial plasma to altitudes above 800 km which then  
19 diffuses down magnetic field lines to form dense bands of plasma on either  
20 side of the magnetic equator at low latitudes (about  $15^\circ$  north and south of  
21 the dip equator). This is known as the equatorial ionospheric anomaly (EIA)  
22 (Appleton, 1954; Anderson, 1981). The vertical ion drift, whose velocity is  
23  $\mathbf{E} \times \mathbf{B}/B^2$  provides the opportunity to directly measure the EEF from Doppler  
24 shifts in radar echoes.

25 While the EEF is responsible for many important ionospheric processes, it  
26 has been difficult to measure or infer the electric field until recently. The JU-  
27 LIA (Jicamarca Unattended Long-term Investigations of the Ionosphere and  
28 Atmosphere) radar at the Jicamarca Radio Observatory has been measuring  
29 150-km drift echoes, from which the EEF can be inferred, since 1996 (Hysell  
30 et al., 1997). While other radars have made similar measurements during var-  
31 ious campaigns, JULIA is the only radar to have continuously measured the  
32 EEF over a long period of time. While the JULIA data have been used in  
33 many studies of the equatorial ionosphere (Fejer and Scherliess, 1997; Batista  
34 et al., 1996), they do not give a global picture of the EEF due to the fixed  
35 location of the observatory near Lima, Peru.

36 Recent satellite missions have for the first time made it possible to make global  
37 measurements of the equatorial electric field in all longitudes, local times, and  
38 seasons. Fejer et al. (2008) have constructed a global climatological vertical  
39 plasma drift model based on observations from the Ionospheric Plasma and  
40 Electrodynamics Probe Instrument (IPEI) aboard the ROCSAT-1 satellite,  
41 during the period from March 1999 to June 2004. Alken and Maus (2007)  
42 created a climatological model of the peak equatorial electrojet current based  
43 on magnetic field observations from the CHAMP, Ørsted and SAC-C satellites.  
44 While this model accurately predicts the climatology of the peak EEJ current,  
45 it does not take into account the full meridional structure of the EEJ current  
46 and therefore does not contain enough information to make estimates of the  
47 EEF.

48 In this study, we use the full latitudinal current structure of the equatorial  
49 electrojet current, as seen by the CHAMP satellite, to predict the eastward  
50 equatorial electric field for individual CHAMP equatorial passes. Previously,

51 Maus et al. (2007) studied CHAMP meridional current profiles averaged over  
52 all longitudes and seasons and attempted to estimate average electric field  
53 values as well as neutral wind profiles. They found difficulties, however, in  
54 separating the individual effects of the winds and the electric field. Alken et al.  
55 (2008) extended this work by using a much improved Horizontal Wind Model  
56 (HWM07). This eliminated the need to co-estimate the winds and therefore  
57 yielded more accurate electric field values for averaged CHAMP profiles. In  
58 this study, we extend this work to individual CHAMP passes, thereby creating  
59 a data set of over 32,000 EEF estimates at all longitudes, seasons and day-side  
60 local times during the years 2000 through 2006.

61 In section 2 we discuss the CHAMP data used for this study. In section 3  
62 we describe our method of modeling the CHAMP EEJ meridional current  
63 profiles and the procedure of producing an electric field estimate. In section 4  
64 we compare the estimates with vertical drift measurements from the JULIA  
65 radar. In section 5 we outline the main global features of the eastward electric  
66 field. Finally, in section 6 we make some concluding remarks.

## 67 **2 CHAMP data**

68 The CHAMP (CHAllanging Minisatellite Payload) satellite was launched into  
69 a polar circular orbit in July 2000 with an initial altitude of 454 km. Its  
70 mean altitude subsequently decayed to about 350 km by the end of 2006. The  
71 satellite completes an orbit every 92 minutes and decreases one hour in local  
72 time every eleven days. The instruments used in this study are the scalar  
73 magnetometer which measures the magnetic field intensity, and the vector  
74 magnetometer whose orientation in space is determined by a dual-head star

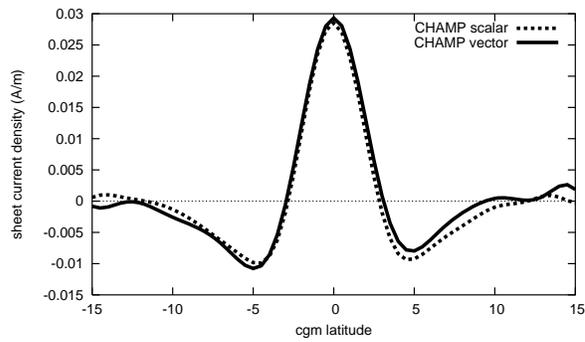

Fig. 1. Sample EEJ current profiles from CHAMP satellite scalar and vector magnetometer data

75 camera.

76 Each time CHAMP flies over the dip equator on the day-side, it records a lati-  
 77 tudinal magnetic profile from which the EEJ signature can be recovered (Lühr  
 78 et al., 2004). First, the POMME-3.1 (Maus et al., 2006) model is subtracted  
 79 which removes contributions from the core, mantle, crust and magnetosphere.  
 80 The remaining residual magnetic signal is primarily due to the Sq current  
 81 and the equatorial electrojet. To remove the Sq contribution, a background  
 82 Sq signal was fitted outside a  $\pm 12^\circ$  window around the dip equator and then  
 83 subtracted to obtain a clean EEJ magnetic signal. To recover the current from  
 84 the magnetic data, we inverted for parallel line currents at 108 km altitude  
 85 with each line current representing  $0.5^\circ$  wide band of height integrated east-  
 86 ward current in corrected geomagnetic (cgm) coordinates (Richmond, 1995).  
 87 Due to difficulties in separating the background magnetic field, there is some  
 88 ambiguity in the zero level current. To overcome this problem, independent  
 89 inversions of the scalar and vector data were done to validate a common zero  
 90 level (Alken and Maus, 2007). These independent inversions are in good agree-  
 91 ment, as shown in Figure 1.

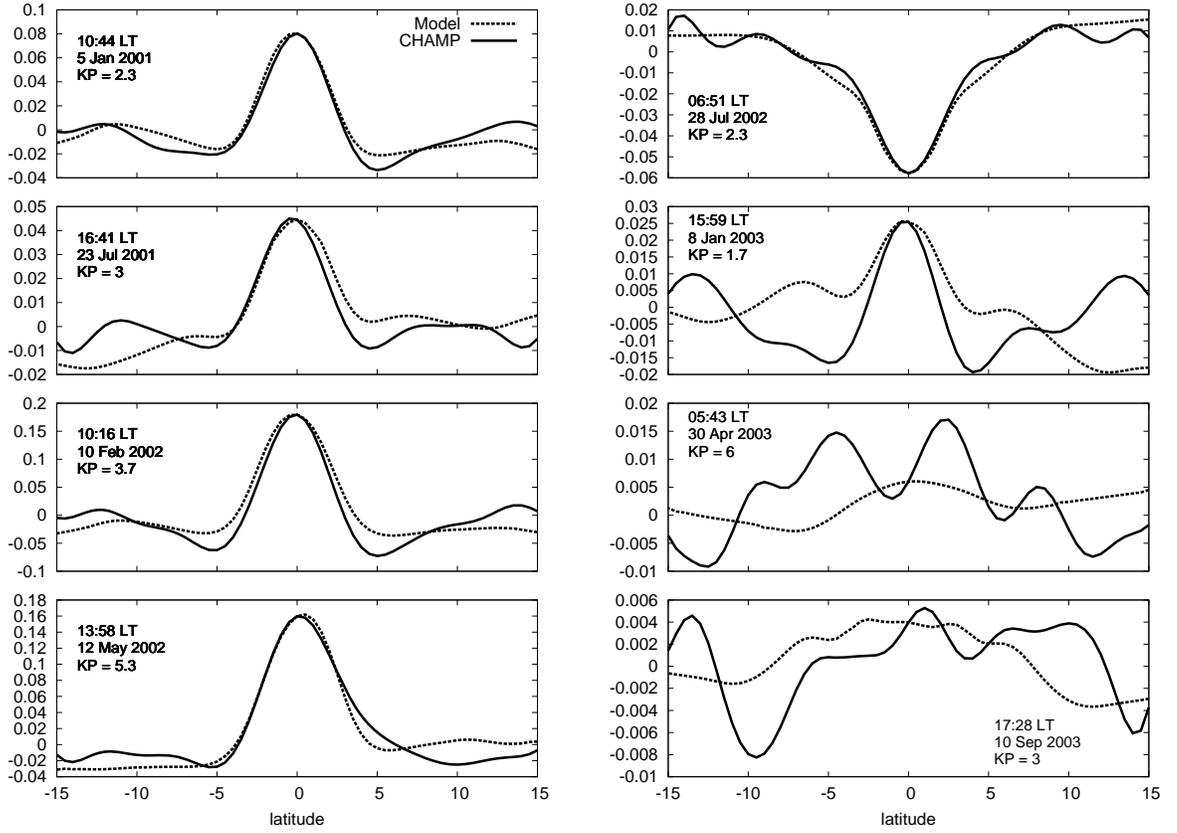

Fig. 2. A random sample of individual CHAMP current profiles (solid) with the corresponding modeled profiles (dotted).

93 are (in geocentric spherical coordinates)

94

$$\nabla \times \mathbf{E} = 0 \quad (1)$$

$$\mathbf{J} = \nabla \times (\psi' \hat{\phi}) + J_{\phi} \hat{\phi} = \sigma (\mathbf{E} + \mathbf{u} \times \mathbf{B}) \quad (2)$$

95 where  $\mathbf{E}$  is the electric field,  $\mathbf{J}$  is the current density,  $\psi'$  is an unknown stream  
 96 function to be determined,  $\hat{\phi}$  is a unit vector in the eastward direction,  $\sigma$   
 97 the conductivity tensor (Forbes, 1981, eq. 10),  $\mathbf{u}$  is the neutral wind velocity,  
 98 and  $\mathbf{B}$  is the ambient magnetic field. Eq. 1 follows from Maxwell's steady  
 99 state conditions and Eq. 2 follows from the steady state momentum equations  
 100 (Forbes, 1981, pgs. 479-480).

101 To model the current density  $\mathbf{J}$ , we first replace the unknown stream function

151 we can use

152

$$J_{PDE}(E_{\phi_0}, \mathbf{u}) = J_{PDE}(E_{\phi_0}, \mathbf{u} = 0) + J_{PDE}(E_{\phi_0} = 0, \mathbf{u}), \quad (17)$$

153 which allows us to set up the CHAMP inversion as

154

$$J_{CHAMP} = sJ_{PDE}(E_{\phi_0}, \mathbf{u} = 0) + J_{PDE}(E_{\phi_0} = 0, \mathbf{u}) - J_{DC} \quad (18)$$

155 where the parameters to be optimized are the scaling factor  $s$  and a possible

156 DC offset  $J_{DC}$ .

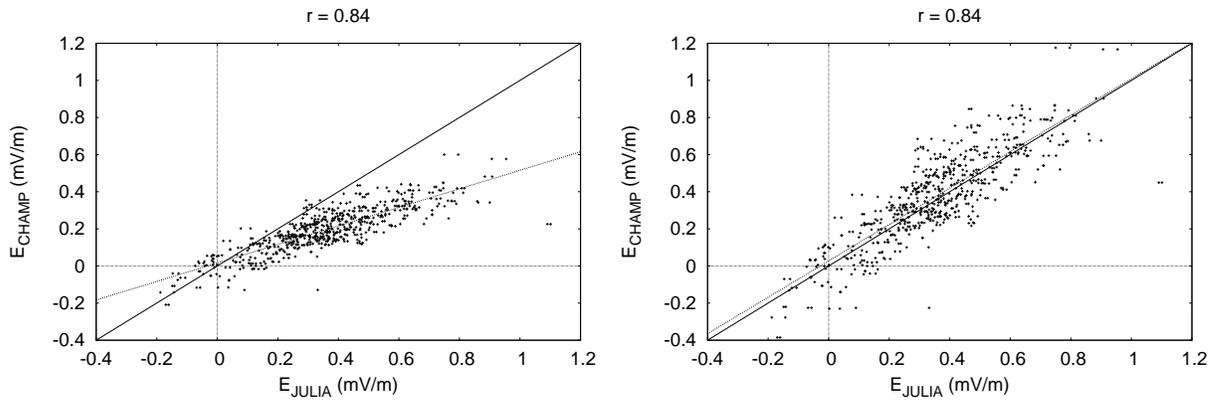

Fig. 3. Comparison of electric field estimates from CHAMP with electric field measurements from the JULIA radar. Best fit line is dotted,  $y = x$  line is solid. Left: CHAMP estimates using unmodified electron collision frequency from NRLM-SISE-00 and IRI2007 models. Best fit line:  $E_{CHAMP} = 0.50 \times E_{JULIA} + 0.02$ . Right: CHAMP estimates using electron collision frequency enhanced by a factor of 4. Best fit line:  $E_{CHAMP} = 0.98 \times E_{JULIA} + 0.03$ .

157 The PDE in Eq. (9) is solved twice for each CHAMP profile, once with the

158 wind input set to 0, and once with the eastward electric field input set to

159 0. The CHAMP profile inversion in Eq. (18) is performed by a least squares

160 method where the parameters  $s$  and  $J_{DC}$  are constrained to make the PDE

161 and CHAMP profiles agree at the magnetic equator. This is done because the  
162 value of the eastward current at the magnetic equator is primarily due to the  
163 eastward electric field, while the winds have more of an effect off of the equator  
164 (Fambitakoye et al., 1976, Figs. 1, 2). The most accurate electric field estimate  
165 is obtained by constraining the PDE solution to agree with CHAMP at the  
166 magnetic equator, verified by comparing exact overflights with the JULIA  
167 radar (see below). There may be some errors introduced with this procedure  
168 in some longitude sectors since the CHAMP current profiles were computed in  
169 corrected geomagnetic coordinates (cgm) but we solve our PDE in geocentric  
170 coordinates. In a follow-on study we plan to extend our modeling to cgm  
171 coordinates to eliminate any possible errors arising from this.

172 Some sample individual CHAMP profiles along with their corresponding mod-  
173 eled solutions are shown in Figure 2. These profiles include the  $4\nu_e$  correction  
174 which is described in more detail below. The majority of modeled profiles  
175 agree well with their CHAMP counterparts. 60% of the modeled profiles had  
176 a correlation with CHAMP of above 0.7. Of those profiles with poor correla-  
177 tions, some were taken during the evening when the EEJ current signal is very  
178 small, causing errors to amplify. Some are simply the result of the difficulties  
179 in modeling day to day highly variable data, especially since our conductivity  
180 and wind models are climatological.

#### 181 **4 Comparison with JULIA vertical drift measurements**

182 To verify our method of modeling the EEF, we compare our results with the  
183 vertical drift measurements of the JULIA radar. JULIA is a coherent scatter  
184 radar data acquisition system located at the Jicamarca Radio Observatory

185 (11.95°S, 76.87°W), which makes high quality measurements of 150-km drift  
186 echoes.

187 Upon initially comparing the results of our modeling process with the JULIA  
188 data, we found that the CHAMP electric field values systematically under-  
189 estimated JULIA EEF estimates by about a factor of 2. Gagnepain et al.  
190 (1977) found when comparing early EEJ models that the observed value of  
191 the electron collision frequency had to be multiplied by a factor of 4 in order  
192 to produce results which accurately reflected observed parameters of the EEJ.  
193 Ronchi et al. (1990) then put this ad hoc assumption on a firmer theoretical  
194 footing by demonstrating that the inclusion of small scale turbulence effects  
195 on the larger scale plasma dynamics, which were not previously taken into ac-  
196 count, enhances the electron Pederson mobility and reduces the polarization  
197 electric field. These effects can be modeled by increasing the observed electron  
198 collision frequency.

199 In this study, we adopted the convention of increasing the electron collision fre-  
200 quency (as computed by the NRLMSISE-00 and IRI2007 models) by a factor  
201 of 4. This method is also utilized by the TIEGCM model in simulations of the  
202 EEJ (Fang, 2008). The resulting zonal electric field estimates from CHAMP  
203 are in impressive agreement with the electric field measurements from JULIA,  
204 as shown in Figure 3. As can be seen, the CHAMP eastward electric field es-  
205 timates are drastically improved with the higher electron collision frequency.  
206 These plots were generated from all available JULIA and CHAMP data from  
207 1 Aug 2001 to 26 November 2006. Data were selected in the local-time sector  
208 0700 to 1600 LT and whenever CHAMP passed within 10° longitude of the  
209 JULIA radar location. These criteria led to 628 CHAMP equatorial crossings.  
210 Figure 3 shows data for all values of Kp, providing some confirmation that our

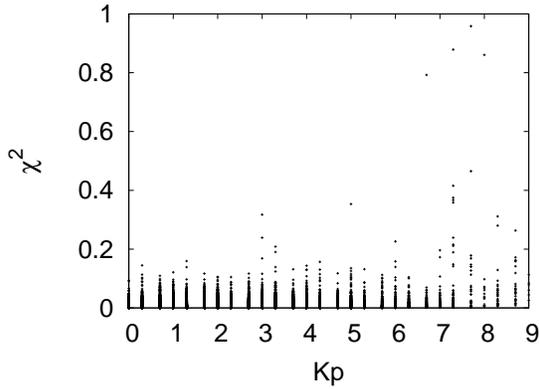

Fig. 4. Misfit between CHAMP current profiles and corresponding modeled profiles as a function of Kp

211 modeling process yields accurate electric field estimates during both quiet and  
 212 disturbed times. We find a correlation coefficient of 0.84 for both the original  
 213 and modified electron collision frequencies. With the modified collision fre-  
 214 quency, the slope of the best fit line remarkably improved to 0.98, close to the  
 215 ideal value of 1.0, indicating that our modeled electric field values agree well  
 216 with the JULIA data. The RMS difference between the CHAMP electric field  
 217 estimates and JULIA values is 0.13 mV/m. While the  $4\nu_e$  correction produces  
 218 very accurate results in the Peruvian sector, the validity of this adjustment at  
 219 other longitudes still needs to be verified. All subsequent figures in this paper  
 220 include the  $4\nu_e$  correction.

221 To further investigate the sensitivity of our modeling procedure to Kp, we show  
 222 in Figure 4 the error  $\chi^2$  between the CHAMP profiles and their corresponding  
 223 modeled profiles as a function of Kp. The misfit function is defined as

$$224 \quad \chi^2 = \sum_i [J_{CHAMP}(\theta_i) - J_{PDE}(\theta_i)]^2 \quad (19)$$

225 where the sum is taken over the latitude range  $-15^\circ$  to  $15^\circ$ , and the term  $J_{PDE}$   
 226 is the full modeled solution, using the optimized eastward electric field value,

227 wind contributions and DC offset. Remarkably the maximum misfit between  
 228 the observed and modeled profiles remains relatively constant except for a few  
 229 disturbed profiles in the range  $7 \leq Kp \leq 9$ .

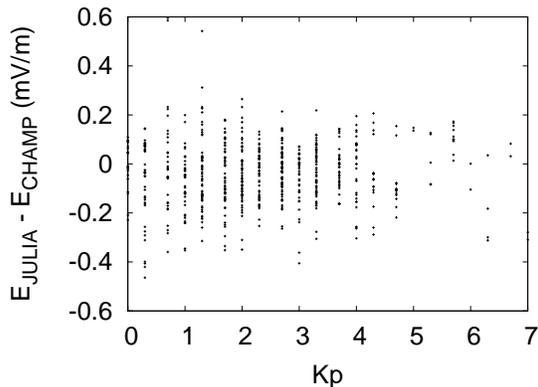

Fig. 5. Difference between CHAMP electric field estimates and corresponding JULIA data as a function of Kp

230 It is also instructive to compare our electric field measurements directly with  
 231 JULIA as a function of Kp. This is shown in Figure 5. Again we used all  
 232 available CHAMP passes over the JULIA radar within  $\pm 10^\circ$ . We see that the  
 233 difference between the JULIA electric field values and the CHAMP estimates  
 234 does not significantly increase with Kp.

235 A further important consideration is how daily departures of ionospheric and  
 236 thermospheric parameters from the climatological mean given by the IRI2007  
 237 and NRLMSISE-00 models may affect our electric field estimates, since the  
 238 conductivity tensor  $\sigma$  is computed entirely from these two models. We exam-  
 239 ined a single CHAMP current profile and varied the relevant IRI and MSIS  
 240 parameters to determine the corresponding uncertainties in the electric field  
 241 estimate. Varying the electron temperature by  $\pm 50\%$  leads to about a  $\pm 10\%$   
 242 change in the electric field estimate. Increasing the electron density from IRI  
 243 by 50% leads to a  $-20\%$  change in the EEF estimate, while decreasing it by

244 50% leads to a +47% change. Changing the electron collision frequency by  
 245  $\pm 50\%$  (before the factor 4 correction) leads to a change of about 30% in the  
 246 EEF estimate. Changing the ion collision frequencies by  $\pm 50\%$  leads to a max-  
 247 imum change in the estimate by about 30%. The neutral densities obtained  
 248 from MSIS lead to less than a 5% difference in the EEF estimate when varied  
 249 by  $\pm 50\%$ . It is remarkable that errors in the neutral density model have such  
 250 a small effect on our EEF estimate and so we conclude that the main source  
 251 of error in our conductivity will come from the IRI model, especially in the  
 252 calculation of the electron/ion densities.

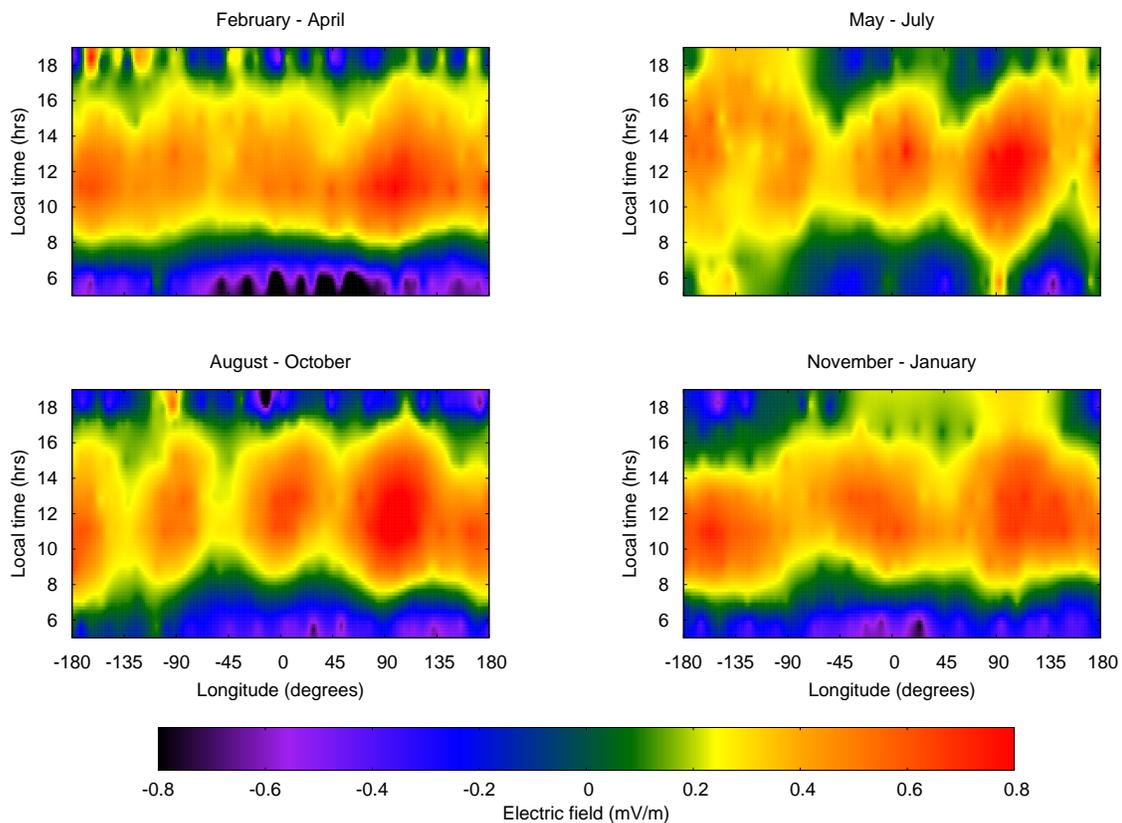

Fig. 6. Electric field as a function of longitude and local time for different seasons at low  $K_p$  ( $\leq 3$ ).

253 We also considered departures of the daily wind field from the Horizontal Wind  
 254 Model, and their effects on our EEF estimates. We examined the effects of the

255 zonal and meridional winds separately, and scaled the winds by a constant  
256 factor at all altitudes of interest. When scaling the zonal winds by  $\pm 50\%$  at  
257 all altitudes, we find a difference of  $\pm 17\%$  in the EEF estimate. The meridional  
258 winds had a much smaller effect, as expected. Scaling these winds by  $\pm 50\%$  at  
259 all altitudes leads to less than a  $1\%$  difference in the EEF estimate. The storm  
260 time component of the Horizontal Wind Model was not included in this study.  
261 In a future study we plan to include disturbance wind effects which may help  
262 to further reduce errors during storm-time conditions.

## 263 5 Global Features of the Eastward Electric Field

264 In Figure 6 we plot the eastward electric field estimates as a function of lon-  
265 gitude and local time for all four seasons during quiet-time ( $K_p \leq 3$ ). Dur-  
266 ing equinox and June solstice we see the well known wavenumber-4 struc-  
267 ture as well as the wavenumber-3 structure during December solstice. The  
268 wavenumber-4 longitudinal structure has been observed in many different data  
269 sets. England et al. (2006) found a wavenumber-4 structure in the peak noon-  
270 time equatorial electrojet current values derived from the CHAMP, SAC-C  
271 and Ørsted satellites. Alken and Maus (2007) later constructed a climatolog-  
272 ical model of the peak EEJ current densities which clearly exhibits a wave-4  
273 structure during equinox and June solstice, as well as a wave-3 structure dur-  
274 ing December solstice. Hartman and Heelis (2007) also found a wavenumber-4  
275 structure in equatorial vertical ion drift measurements of the DMSP satel-  
276 lite (830 km altitude) in the 0930 local time sector during September. Fejer  
277 et al. (2008) recently constructed a climatological vertical plasma drift model  
278 from ROCSAT-1 measurements which also exhibits the wave-4 and wave-3

279 structures at different seasons.

280 Recent studies attribute the wavenumber-4 longitudinal pattern to the east-  
281 ward propagating diurnal tide with zonal wavenumber-3 (DE3) originating in  
282 the tropical troposphere. Lühr et al. (2008) performed a detailed analysis of  
283 the effects of DE3 on the equatorial electrojet using the climatological model  
284 EEJM-1 of Alken and Maus (2007). They found that DE3 is the primary con-  
285 tributor to longitudinal variations in the EEJ, especially during the months  
286 April - October.

287 We find longitudinal peaks during both equinoxes near  $-170^\circ$ ,  $-90^\circ$ ,  $0^\circ$ , and  
288  $100^\circ$  longitude, in agreement with the findings of Alken and Maus (2007)  
289 and Fejer et al. (2008). Also significant is the strength of the EEF during  
290 September equinox as compared to March equinox. This feature is also seen  
291 in the magnetic data from CHAMP but was not incorporated into the seasonal  
292 dependence in the model of Alken and Maus (2007). During December solstice  
293 we see peaks near  $-170^\circ$ ,  $0^\circ$  and  $100^\circ$  also in agreement with Fejer et al. (2008).  
294 In June solstice we find a large peak near  $100^\circ$ , a much smaller peak near  $10^\circ$   
295 and a broad peak in the longitudinal sector  $-180^\circ$  to  $-90^\circ$  which appears as  
296 a double peak during the 0800 to 1400 local time sector, and appears as a  
297 single peak in the early morning and the evening, also in agreement with the  
298 findings of Fejer et al. (2008).

299 In Figure 7 we plot the electric field as a function of longitude and season  
300 around 1200 LT for quiet-time ( $K_p \leq 3$ ). Here we see that the electric field  
301 is strongest during September equinox, especially at the  $100^\circ$  peak. The peak  
302 at  $-170^\circ$  tends to be stronger closer to December solstice and into January.  
303 The peak at  $-170^\circ$  appears to drift to around  $-150^\circ$  during December solstice

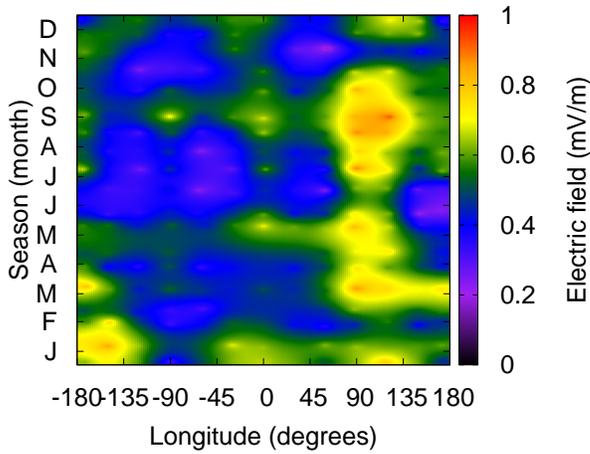

Fig. 7. Electric field as a function of longitude and season for 1100 to 1300 local time at low  $K_p$  ( $\leq 3$ ).

304 leading to the wave-3 structure we observe. The seasonal dependence of the  
 305 electric field is further illustrated in Figure 8 where we plot the raw data for the  
 306 1100 to 1300 local time sector near the longitudes  $-170^\circ$  and  $100^\circ$ , along with  
 307 a smoothed data curve. Here we see a large peak during September equinox  
 308 in the  $80^\circ$  to  $110^\circ$  longitude sector with smaller peaks during January, March  
 309 equinox, May, July, and December solstice. In the  $-180^\circ$  to  $-160^\circ$  longitude  
 310 sector, we find stronger peaks in January and March equinox with four smaller  
 311 peaks during May, July, September equinox and November. Though our data  
 312 appears to exhibit a six peak structure in season, some of these features may  
 313 be caused by a lack of CHAMP data at all seasons near 1200 LT, and further  
 314 study is required to determine if these features are physically real.

315 In Figure 9 we plot the eastward electric field as a function of local time and  
 316 season for the longitudinal peak near  $100^\circ$ . We find that the EEF has a broad  
 317 peak in the 1000 to 1400 local time sector during all seasons. We again see  
 318 multiple seasonal peaks in the data, especially around local noon, but again

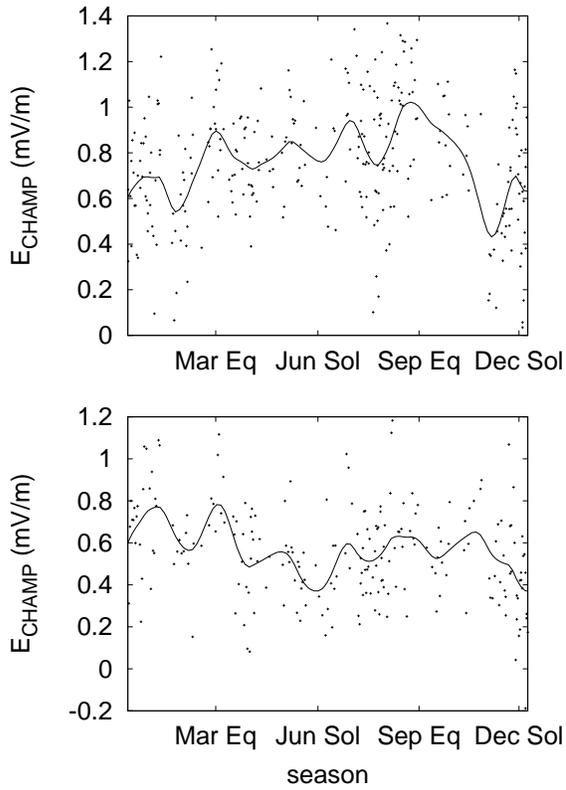

Fig. 8. Electric field as a function of season for 1100 to 1300 local time at low  $K_p$  ( $\leq 3$ ). Top: all data for the longitude sector  $80^\circ$  to  $110^\circ$ . Bottom: all data for the longitude sector  $-180^\circ$  to  $-160^\circ$ . The solid curve in both plots represents a smoothing of the data by Tikhonov regularization.

319 we caution this could be due to noise or an insufficient amount of data.

320 We show a clearer picture of the local time dependence in Figure 10. Here  
 321 we plot our raw electric field estimates as a function of local time during  
 322 September equinox with a smoothed data curve. In the upper plot we display  
 323 the peak occurring at  $100^\circ$  by taking all data in the longitude sector  $80^\circ$  to  
 324  $110^\circ$ . The bottom plot represents the peak occurring near  $0^\circ$  by taking data in  
 325 the longitude sector  $-10^\circ$  to  $20^\circ$ . In both cases we see a westward electric field  
 326 in the early morning hours and a steady rise to a broad peak around 1000 to  
 327 1400 LT. The electric field then steadily decreases to zero at about 1800 LT.

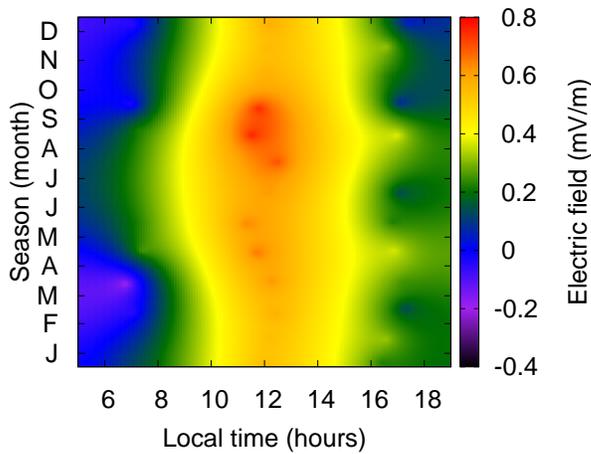

Fig. 9. Electric field as a function of local time and season for  $80^{\circ}$  to  $110^{\circ}$  longitude at low  $K_p$  ( $\leq 3$ ).

## 328 6 Discussion

329 We have successfully implemented a procedure to solve the differential equa-  
 330 tions governing the equatorial electrojet in conjunction with observed CHAMP  
 331 satellite meridional EEJ current profiles to produce estimates of the eastward  
 332 electric field. We have constructed a data set of over 32,000 electric field esti-  
 333 mates with coverage of all longitudes, seasons, and day-time local times. Our  
 334 estimates were compared with vertical drift measurements from the JULIA  
 335 coherent scatter radar at Jicamarca, Peru, finding a high correlation of 0.84  
 336 as well as a best fit slope of 0.98 between the JULIA electric field measure-  
 337 ments and our estimates based on CHAMP. Our analysis has been carried  
 338 out during both quiet and disturbed times, and we find good agreement with  
 339 JULIA even during highly disturbed times. The RMS difference between the  
 340 JULIA and CHAMP-derived electric field values is 0.13 mV/m. For this error  
 341 estimate, no data were excluded for any reason.

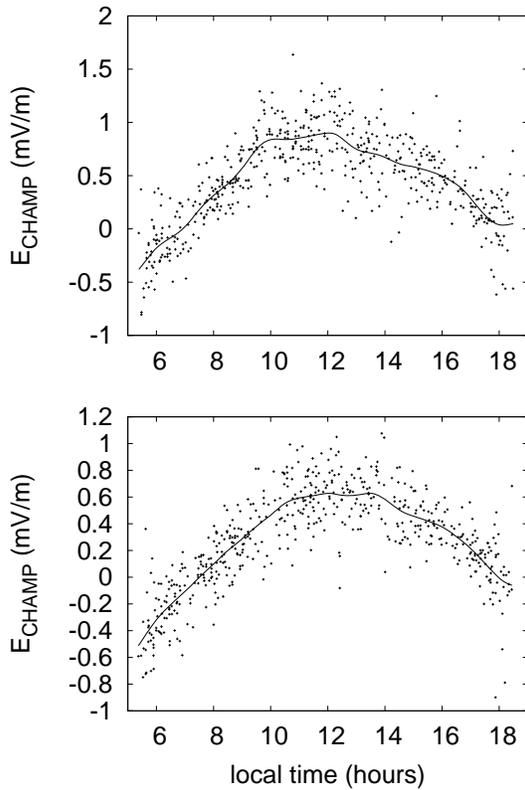

Fig. 10. Electric field as a function of local time during September equinox at low  $K_p (\leq 3)$ . Top: all data for the longitude sector  $80^\circ$  to  $110^\circ$ . Bottom: all data for the longitude sector  $-10^\circ$  to  $20^\circ$ . The solid curve in both plots represents a smoothing of the data by Tikhonov regularization.

342 We have shown that our electric field estimates exhibit previously identified  
 343 behavior in longitude, local time, and season. We find the well known wave-  
 344 4 and wave-3 longitudinal structures at different seasons in agreement with  
 345 several previous studies (England et al., 2006; Alken et al., 2008). Seasonally,  
 346 we find peaks in the EEF during equinox at most longitudes as well as a much  
 347 stronger field during September equinox compared to March equinox. In local  
 348 time, we find a westward electric field in the early morning and a broad peak  
 349 in the EEF around 1000 to 1400 LT.

350 We have examined the effects of errors in the IRI-2007, NRLMSISE-00 and

351 HWM07 models on our EEF estimates. We find that the largest changes in our  
352 EEF estimates will come from daily variations in the electron/ion densities,  
353 the electron/ion collision frequencies, and the zonal winds. Variations in the  
354 electron temperature, neutral densities, and meridional winds have very little  
355 effect on the EEF estimates. In all cases, uncertainties in ionospheric and  
356 thermospheric parameters lead to a smaller corresponding effect on the electric  
357 field estimates as required for a reliable modeling method.

358 As mentioned before, vertical wind effects were not included in this study.  
359 Vertical winds can have a substantial effect on vertical polarization electric  
360 fields and consequently the zonal electric field in the  $E$ -region (Hysell et al.,  
361 2002). Anandarao et al. (1978) report up to 20 m/s vertical winds in the  
362 equatorial region at altitudes of 95-100 km. These winds could have large  
363 effects on the equatorial electrojet, and possibly even cause counter-electrojet  
364 conditions (Raghavarao and Anandarao, 1980). Unfortunately very few studies  
365 exist on vertical wind effects at the equator, and those that do normally have  
366 data for only a few heights and rely on considerable extrapolation (Anandarao  
367 et al., 1978). Therefore, due to a lack of data and models, we are unable to  
368 include vertical wind effects in our present study.

369 Overall we believe our method to be a significant advance in the study of  
370 equatorial electrodynamics. This work will open possibilities for future studies  
371 into the climatology of the EEF, studies of the EEF during disturbed times,  
372 as well as the study of the many ionospheric phenomena influenced by the  
373 EEF.
